Keywords: Photocatalysis Pollutionabatement Polyoxoanion Tolueneoxidation

ABSTRACT

A new photocatalyst $(Na_4W_{10}O_{32}/SiO_2/BTESE)$ has been prepared by simultaneous hydrolysis of tetraethyl orthosilicate (TEOS) and 1,2-bis(triethoxysilyl)ethane (BTESE) in the presence of $Na_4W_{10}O_{32}$. This material is able to scavenge and accumulate significant amounts of toluene from water solutions saturated with the hydrocarbon. This is due to its large specific surface area, micro and mesoporosity, and, above all, to the high hydrophobicity of its surface. Moreover, photoexcited $Na_4W_{10}O_{32}/SiO_2/BTESE$ show savery strong oxidizing ability, allowing an almost complete mineralization of toluene to CO_2 through the formation and reactivity of OH^{\bullet} radicals. Considering both the sorption capability and the photocatalytic activity, the efficiency of $Na_4W_{10}O_{32}/SiO_2/BTESE$ is significantly higher than those of $Na_4W_{10}O_{32}/SiO_2$ and $Na_4W_{10}O_{32}$ dissolved in homogeneous solution. At the end of a cycle of reaction, $Na_4W_{10}O_{32}/SiO_2/BTESE$ is reusable without any loss of activity opening to the development of new efficient and stable photocatalytic systems addressed to clean wastewater containing aromatic hydrocarbons.

1. Introduction

Polyoxotungstates (POTs) continue to be the object of intense interest in oxidative photocatalysis [1–4]. This research topic moves towards a "sustainable chemistry" opening to new reaction routes either for syntheses or for wastewater treatments that require O_2 as available and cheap oxidant, mild conditions of temperature and pressure, and use of light as renewable source of energy. Among the POTs investigated, the decatungstate anion $W_{10}O_{32}^{4-}$ presents an absorption spectrum that partially overlaps the UV solar emission, opening the possibility to carry out fine solar-assisted applications [5–9].

The proposed mechanism for decatungstate-based photocatalysis involves absorption of light by the polyanion ground state leading to an oxygen to metal charge-transfer excited state ($W_{10}O_{32}^{4-*}$) [6,10] that decays in few picoseconds to a very reactive transient species (wO). This species has an oxyradical-like character with a longer lifetime (about 50 nanoseconds) and is able to oxidize many substrates to their corresponding radicals with the simultaneous formation of the mono-reduced form of the decatungstate ($W_{10}O_{32}^{5-}$) [3,6]. Oxidation of $W_{10}O_{32}^{5-}$ by O_2 restores the starting $W_{10}O_{32}^{4-}$ and causes dioxygen reductive activation to peroxy species. Moreover, in aqueous solutions, the

formation of highly reactive hydroxyl radicals through the direct reaction between photoexcited polyoxoanions and water was demonstrated [1,11-14]: this process can be described by Eq. (1).

$$wO + H_2O \rightarrow W_{10}O_{32}^{5-} + OH^{\bullet} + H^{+}$$
 (1)

In recent years, heterogenization of $W_{10}O_{32}^{4-}$ on organic and inorganic solid matrices has progressed significantly, and great attention is being devoted to design new photoactive materials in order to control efficiency and selectivity of oxidation processes through the control of the local environment surrounding the photoactive decatungstate cluster [13–31]. More specifically, micro and mesoporous materials, and the appropriate ratio of surface hydrophobic/hydrophilic character are considered helpful for improving the enrichment of substrates in the proximity of the POT.

We reported recently data concerning the entrapment of $Na_4W_{10}O_{32}$ in a silica matrix by hydrolysis of tetraethylorthosilicate (TEOS) for obtaining a good photocatalytic material ($Na_4W_{10}O_{32}/SiO_2$). This system photogenerated hydroxyl radicals that, in turn, were able to induce alcohols oxidation [13,14]. In the present work, the new material $Na_4W_{10}O_{32}/SiO_2/BTESE$ was prepared through simultaneous hydrolysis of TEOS and 1,2-bis(triethoxysilyl)ethane (BTESE). In line with literature data on related systems, this procedure allows to obtain silica characterized by high surface hydrophobicity [32,33]. This was already proved for chromium-modified mesoporous silica, where the hydrophobization enhanced the photoactivity of chromate species in the oxidation of cyclohexane [34,35].

The photocatalytic activity of both $Na_4W_{10}O_{32}/SiO_2$ and $Na_4W_{10}O_{32}/SiO_2/BTESE$ is here investigated for the first time in the oxidation of toluene. We are interested to evaluate the ability of these materials to remove toluene from water and to induce the subsequent photocatalytic degradation of the hydrocarbon to carbon dioxide. Particular attention is devoted to the effect of the organoalkoxysilane on both the entrapping capability and the photocatalytic efficiency of the investigated material.

Toluene is a very noxious organic compound that can be found in several industrial waste emissions. Among the strategies that have been investigated in order to reduce its presence in the environment, photocatalysis with TiO₂ has been employed both in gas-solid [36–38] and in water-solid systems [39,40]. In the second case, a complete photooxidation of toluene has been observed after some hours irradiation with the formation of p-cresol and benzaldehyde as main intermediates [39]. A zwitterionic surfactant is able to trap the toluene molecules close to the TiO₂ photocatalytic surface, so increasing the oxidation rate. The design of porous materials as sorbents for the removal of pollutants such as toluene is another area of research of interest in the wastewater treatments [41]. However, an important limitation of this approach is that the complete recovery of the absorbing materials often requires their thermal treatment at high temperature.

2. Experimental

2.1. Photocatalysts preparation and characterization

Reagents and solvents were purchased from Sigma in the highest purities available and used without further purification. Sodium decatungstate (Na₄W₁₀O₃₂) was synthesized as reported in the literature [31]. The heterogeneous photocatalyst (Na₄W₁₀O₃₂/SiO₂) was prepared by hydrolysis of tetraethyl orthosilicate (TEOS, 23 mmol, 4.8 g) in the presence of an acid aqueous solution of Na₄W₁₀O₃₂, following a procedure published in detail for the entrapment of (nBu4N)4W₁₀O₃₂ inside silica [27]. Na₄W₁₀O₃₂/SiO₂/BTESE has been obtained by the simultaneous hydrolysis of TEOS (23 mmol, 4.8 g) and BTESE (2.3 mmol, 0.8 g). On the basis of the solid mass obtained at the end of the preparation and the initial amount of $Na_4W_{10}O_{32}$ employed (0.5 g), we could estimate that both the prepared materials contained 30% (w/w) of decatungstate. UV-vis spectra of washing water aliquots showed that Na₄W₁₀O₃₂ was not released into the solution. A sample not including the polyanion (SiO₂) was also prepared carrying out the hydrolysis in the absence of decatungstate.

Diffuse reflectance UV-vis spectra were recorded with a Jasco V-570 using an integrating sphere and BaSO₄ as reference. The plotted spectra were obtained by the Kubelka–Munk transformation (F(R) = $1-R^2/2R$) versus the wavelengths. FTIR spectra were obtained by means of Bruker IFS28, Globar source and cryodetector MCT with resolution $4\,\mathrm{cm}^{-1}$. The spectra were obtained in homemade vacuum cell allowing the outgassing of the material (residual pressure of 10^{-4} mbar) and the simultaneous spectroscopic measurement. Materials were prepared in form of self-supporting pellets ($\sim 40\,\mathrm{g/cm}^2$) and in form of thin layers ($\sim 10\,\mathrm{g/cm}^2$) supported on silicon wafer.

 N_2 adsorption–desorption experiments were carried out at 77 K by means of ASAP2020 instrument (Micromeritics). Before each measurement, samples were outgassed overnight at 150 °C with a rotative pump (residual pressure about 10^{-2} mbar).

Microgravimetric adsorption isotherms were obtained at $25\,^{\circ}\mathrm{C}$ with microbalance apparatus (IGA002 by Hiden), contacting the powders with water and toluene vapours. The temperature control was guaranteed by thermostatic bath. Adsorption tests of toluene in liquid phase were also carried out by putting $100\,\mathrm{mg}$ of $Na_4W_{10}O_{32}/SiO_2/BTESE$ or $Na_4W_{10}O_{32}/SiO_2$ in $0.2\,\mathrm{mL}$ of a water

solutions containing toluene. The mixtures were rapidly stirred at room temperature for 30 min. The powder dispersions were, then, centrifuged and the solution analysed by GC. Adsorbed toluene was quantified by its decrease in the solution after the contact with the solid

EPR spin trapping experiments were carried out with a Bruker ER 200 MRD spectrometer equipped with a TE 201 resonator, at a microwave frequency of 9.4 GHz. The samples were constituted by suspensions of one of the two photocatalysts (20 mg) in 1 mL of aqueous solutions of 5,5-dimethylpyrroline *N*-oxide (DMPO $4\times10^{-2}\,\rm M)$ as spin trap, in the presence of toluene $(6\times10^{-3}\,\rm M)$ when requested. Samples were put into a flat quartz cell and directly irradiated (λ > 290 nm) inside the EPR cavity with a Helios Q400 Italquartz medium-pressure Hg lamp. No signals were obtained in the dark and during irradiation of the solution in the absence of photocatalyst.

2.2. Photocatalytic experiments

The photocatalysts Na₄W₁₀O₃₂/SiO₂/BTESE or Na₄W₁₀O₃₂/SiO₂ (100 mg) were kept in contact with 0.2 mL of a saturated water solution of toluene (6×10^{-3} M). After 10 min of stirring the powder suspension was centrifuged. The liquid phase was analysed by gas chromatographic technique in order to establish the amount of toluene still present in the water phase. Then, the material containing toluene was suspended in 0.5 mL of distilled water and irradiated for 30 min inside a 3 mL spectrophotometric cell, upon stirring. Photochemical excitation was performed with a mediumpressure Hg lamp (like that described above). A glass cut-off filter was used for selecting light of wavelengths higher than 290 nm. Measurements with an ultraviolet radiometer indicated that this amount of photocatalyst absorbs more than 90% of the impinging radiation. At the end of the photocatalytic experiment, the sample was centrifuged and the aqueous phase analysed by GC. The irradiated powder was also suspended in aliquots (0.2 mL) of water, acetone, acetonitrile and dichloromethane in order to extract all the products eventually entrapped. Homogeneous photocatalytic experiments were carried out dissolving Na₄W₁₀O₃₂ in a saturated water solution of toluene (3 mL). The decatungstate concentration in this solution (2 \times 10⁻⁴ M) warranted the complete absorption of the incident photons. After irradiation, the samples were analysed as described above.

Product analyses were carried out with a gas chromatograph HP 6890 Series Instrument equipped with a flame ionization detector and a HP-WAX (cross linked polyethylene glycol, 30 m, 0.32 mm \times 0.5 μm film thickness) capillary column. The quantitative analyses were performed with calibration curves obtained with authentic samples.

In order to establish the amount of CO_2 eventually formed, samples containing $Na_4W_{10}O_{32}/SiO_2/BTESE$, $Na_4W_{10}O_{32}/SiO_2$ or $Na_4W_{10}O_{32}$ were irradiated maintaining the reactor firmly closed. At the end of irradiation 2.6 mL of a NaOH solution (0.1 M) were put inside the reactor with a syringe and mixed with the irradiated dispersion. Then, after centrifugation, 2.0 mL of the aqueous phase were taken and kept into a vial. After the addition of 1 mL of saturated citric acid solution, carbon dioxide released was measured by a carbon dioxide ion selective electrode (Thermo Scientific Orion Products). Quantitative analysis was made through a calibration curve built from standard solutions of $NaHCO_3$ treated as described above. Results obtained after irradiation were compared with those coming from analogous samples kept in the dark for the same period. The yield of CO_2 was referred to the number of carbon atoms present in a toluene molecule.

No oxidation products were observed when blank experiments were run in the dark. Other control experiments indicated that irradiation of saturated water solution of toluene in the presence of

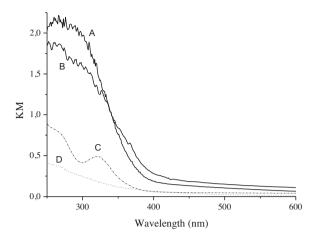

Fig. 1. DR-UV-vis spectra of $Na_4W_{10}O_{32}/SiO_2/BTESE$ (curve A), $Na_4W_{10}O_{32}/SiO_2$ (curve B), $Na_4W_{10}O_{32}$ (curve C) and SiO_2 (curve D).

 SiO_2 without decatung state did not yield appreciable amounts of oxidation products.

Some experiments were carried out in order to test the stability of $Na_4W_{10}O_{32}/SiO_2/BTESE$ in repeated photocatalytic experiments: an aliquot of $100\,\mathrm{mg}$ of photocatalyst has been recycled in subsequent photocatalytic experiments after washing with aliquots of water, acetone, acetonitrile and dichloromethane and drying at $373\,\mathrm{K}$ for $60\,\mathrm{min}$.

3. Results and discussion

3.1. Synthesis and textural characterization

Entrapment of $Na_4W_{10}O_{32}$ in a silica matrix for obtaining $Na_4W_{10}O_{32}/SiO_2$ photocatalyst has been carried out following a

sol–gel procedure previously published [13]. Preparation of the Na₄W₁₀O₃₂/SiO₂/BTESE material is based on the use of BTESE, which hydrolyses together with TEOS [32,34,35]. The preparation of both Na₄W₁₀O₃₂/SiO₂/BTESE and Na₄W₁₀O₃₂/SiO₂ is carried out at pH 2. At this pH value, the silanol groups \equiv Si \equiv OH are protonated to form \equiv Si \equiv OH₂⁺. These species can act, in turn, as counterions for W₁₀O₃₂^{4 \equiv} groups yielding the couple (\equiv Si \equiv OH₂⁺)(Na₃W₁₀O₃₂ \equiv) by acid–base reaction. The interaction established is very strong and the decatungstate groups are no longer released when these materials are dispersed in aqueous medium.

Fig. 1 shows the UV–vis spectra of $Na_4W_{10}O_{32}/SiO_2/BTESE$ and $Na_4W_{10}O_{32}/SiO_2$ (curves A and B, respectively). Spectra of $Na_4W_{10}O_{32}$ (curve C) and of silica support (curve D) are also reported for a sake of comparison. Both $Na_4W_{10}O_{32}/SiO_2/BTESE$ and $Na_4W_{10}O_{32}/SiO_2$ present an intense absorption at wavelengths lower than 400 nm, due to the presence of decatung state.

Gas-volumetric adsorption of N_2 at low temperature can give important information about the specific surface area and the pore size distribution of the $N_4W_{10}O_{32}/SiO_2/BTESE$ system. As far as the surface area is concerned, we characterized this material by means of the BET method [42]. In order to evaluate the porosity eventually close in size to the boundary between micro and mesoporosity regions, we employ here the same method already adopted for the investigation of $N_4W_{10}O_{32}/SiO_2$, which bases on density functional theory (DFT) [27]. Specific surface area and pore volume data of $N_4W_{10}O_{32}/SiO_2/BTESE$ are summarized in Table 1, compared with the results previously published for $N_4W_{10}O_{32}/SiO_2$ [13]. The porosity data, whose relative pore size distributions are shown in Fig. 2, are reported splitted in two contributions, micropores below 10 Å and mesopores above 10 Å of width, on the basis of materials pore distribution.

Table 1 shows that the specific surface area of $Na_4W_{10}O_{32}/SiO_2/BTESE$ is markedly higher than that of its parent material $Na_4W_{10}O_{32}/SiO_2$. It is also seen that the introduction of the

Table 1 Morphological features of $Na_4W_{10}O_{32}/SiO_2$ and of $Na_4W_{10}O_{32}/SiO_2/BTESE$.

Sample	SSA $(m^2 g^{-1})$	$V_{\rm tot}$ (cm ³ g ⁻¹)	$V_{ m micro}$ (<10 Å width, cm ³ g ⁻¹)	$V_{\rm meso}$ (>10 Å width, cm ³ g ⁻¹)

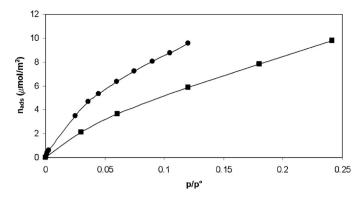

Fig. 3. Microgravimetric adsorption isotherms of water vapour on $Na_4W_{10}O_{32}/SiO_2$ (\bullet) and $Na_4W_{10}O_{32}/SiO_2/BTESE$ (\blacksquare) activated at 25 °C. The adsorption experiments were carried out at 25 °C.

organoalkoxysilane enhances of about 40% the total pore volume. More specifically, this increase is essentially due to an increase of mesoporosity: in fact, $\rm Na_4W_{10}O_{32}/SiO_2/BTESE$ presents a larger amount of pores with width of 13 and 28 Å. These results indicate that the incorporation of BTESE during the synthesis of the silica-based material induces important modification to the porous texture of this material, suggesting that the organoalkoxysilane can act as a templating agent.

3.2. Surface effects

Some experiments have been carried out in order to compare adsorption of water and toluene on Na₄W₁₀O₃₂/SiO₂/BTESE and Na₄W₁₀O₃₂/SiO₂. As shown in Fig. 3, water vapour is better adsorbed on the surface of Na₄W₁₀O₃₂/SiO₂, whereas the adsorption observed on Na₄W₁₀O₃₂/SiO₂/BTESE is more limited. It suggests that the synthesis with BTESE makes the surface of silica more hydrophobic, as observed for other similar materials [33,35]. This is in line with FTIR spectra (Fig. 4), obtained on self-supporting pellets (to observe CH signals) and on thin layers (to observe OH signals), indicating the presence of organic fragments still present after calcination treatment. Analogously, also OH groups are still visible in the spectra, and they could be responsible for the not

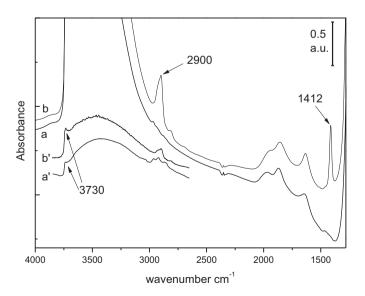

Fig. 4. FTIR spectra relative to Na₄W₁₀O₃₂/SiO₂ (curve a) and Na₄W₁₀O₃₂/SiO₂/BTESE (curve b). Curves a' and b' refer to the same samples in form of thin layers (deposition on Si wafer). The arrows in figure indicate the main signals due to the modifier (ν_{CH} at 2900 and δ_{CH} at 1412 cm⁻¹) and to silica hydroxyls (ν_{OH} at 3730 cm⁻¹).

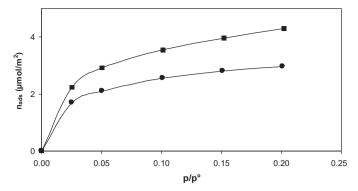

Fig. 5. Microgravimetric adsorption isotherms of toluene vapour on $Na_4W_{10}O_{32}/SiO_2$ (\bullet) and $Na_4W_{10}O_{32}/SiO_2/BTESE$ (\blacksquare) activated at $25\,^{\circ}$ C. The adsorption experiments were carried out at $25\,^{\circ}$ C.

negligible interaction observed with water molecules. Therefore, the calcination temperature was not high enough to induce the complete removal of BTESE precursor and the elimination of silanols with subsequent formation of siloxane groups (Si–O–Si) [43].

Toluene adsorption data confirm the hydrophobic character of $Na_4W_{10}O_{32}/SiO_2/BTESE$ surface compared to $Na_4W_{10}O_{32}/SiO_2$ one. Toluene adsorption isotherms were obtained via microgravimetric analysis using toluene in vapour phase as adsorptive (Fig. 5) and via GC from toluene aqueous solution (Fig. 6). Analogous trends were obtained, although the extent of adsorption is dramatically enhanced in the case of adsorption from vapour phase. A possible explanation of this phenomenon can be ascribed to the different ability of molecules to penetrate in the void space (pores) in gas and liquid phase: in the gas phase, the naked molecules can interact more easily than in the corresponding solvated situation.

3.3. Hydroxyl radicals formation

EPR spin-trapping investigation is a powerful technique for detecting the formation of short-lived radicals and has been fruitfully employed in photochemical studies on polyoxometalates in order to better understand photochemical primary processes [13,14,44,45]. The technique is based on the ability of some molecules, such as nitrones, to trap radicals to give nitroxides stable enough to be successfully detected and characterized. The nature of the trapped radical can be often identified by the parameters obtainable from the EPR spectrum.

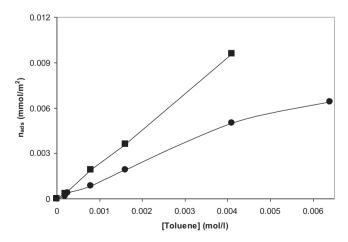

Fig. 6. Toluene adsorption isotherms from liquid phase on Na₄W₁₀O₃₂/SiO₂/BTESE (\blacksquare) and Na₄W₁₀O₃₂/SiO₂ (\bullet).

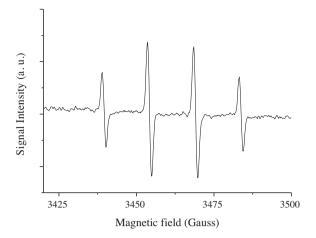

Fig. 7. EPR spectrum of [DMPO-OH]* obtained upon irradiation (λ > 290 nm) of Na₄W₁₀O₃₂/SiO₂/BTESE dispersed in water containing DMPO (4×10^{-2} M).

Evidences of the formation of OH• radicals as a consequence of photoexcitation of Na₄W₁₀O₃₂/SiO₂ in aqueous system were previously obtained using 5,5-dimethylpyrroline *N*-oxide (DMPO) as a spin trap [13,14]. This species is able to react with OH• radicals according to Eq. (2) to form the paramagnetic adduct [DMPO-OH]•, whose typical spectrum consists of a quartet 1:2:2:1 ($a_N = a_H = 14.5 \text{ G}$) [46]. The formation of OH• radicals in that photocatalytic system were ascribed to both the direct water oxidation (Eq. (1)) and the reaction between the photogenerated W₁₀O₃₂⁵⁻ and H₂O₂ (Eq. (3)), which must be included among the products of the reoxidation process of W₁₀O₃₂⁵⁻ by O₂ [14].

$$DMPO + OH^{\bullet} \rightarrow [DMPO-OH]^{\bullet}$$
 (2)

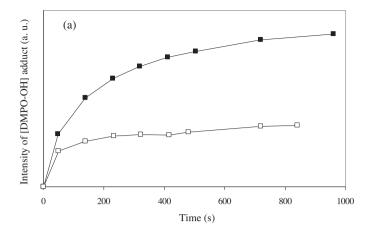

$$H_2O_2 + W_{10}O_{32}^{5-} \rightarrow W_{10}O_{32}^{4-} + OH^{\bullet} + OH^{-}$$
 (3)

The EPR spin-trapping investigation indicates that OH $^{\bullet}$ radicals are formed also as a consequence of photoexcitation of Na₄W₁₀O₃₂/SiO₂/BTESE. In fact, Fig. 7 shows that illumination (λ > 290 nm) of this material in aqueous suspensions containing DMPO(4×10^{-2} M) causes the prompt formation of a quartet whose signal pattern and coupling constant values are in agreement with the trapping of OH $^{\bullet}$ radicals by DMPO, according to Eq. (2) [46]. Control experiments show that no signal is observed neither in the dark nor during irradiation in the absence of photocatalyst.

Fig. 8a compares the intensity of the [DMPO-OH]• adduct in time upon irradiation of $Na_4W_{10}O_{32}/SiO_2/BTESE$ in the absence and in the presence of toluene. The addition of toluene causes a strong decrease of the intensity of the EPR signal, indicating that this molecule is a very good competitor for the reaction with OH• radicals in respect to the spin trap species. This is not surprising considering that adsorption phenomena on the hydrophobic surface of $Na_4W_{10}O_{32}/SiO_2/BTESE$ favour the access of toluene into the silica framework in proximity of the photoactive decatungstate. Accordingly, the presence of toluene does not cause appreciable changes in the [DMPO-OH]• signal intensity during irradiation of the more hydrophilic $Na_4W_{10}O_{32}/SiO_2$ photocatalyst, as indicated by the curves reported in Fig. 8b.

3.4. Toluene entrapment and photodegradation

Continuous irradiations of $Na_4W_{10}O_{32}/SiO_2$ and $Na_4W_{10}O_{32}/SiO_2/BTESE$ systems in toluene saturated water solutions have been carried out in order to investigate the reactivity of the photogenerated OH $^{\bullet}$ radicals. Likely, these oxidizing species can be able to initiate toluene oxidation that, upon aerobic conditions, leads to

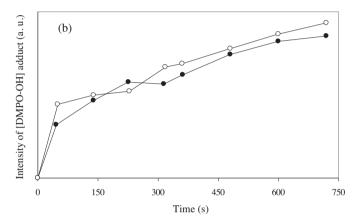

Fig. 8. Fixed-field signal intensity of the [DMPO-OH]* adduct in time upon irradiation ($\lambda > 290$ nm) of: (a) Na₄W₁₀O₃₂/SiO₂/BTESE dispersed in water containing DMPO (4×10^{-2} M, full squares) and in an analogous solution containing also toluene (6×10^{-3} M, empty squares), (b) Na₄W₁₀O₃₂/SiO₂ dispersed in water containing DMPO (4×10^{-2} M, full circles) and in an analogous solution containing also toluene (6×10^{-3} M, empty circles).

the formation of oxygenated products and, finally, to the complete mineralization to carbon dioxide and water.

Before photochemical excitation, Na₄W₁₀O₃₂/SiO₂/BTESE or Na₄W₁₀O₃₂/SiO₂ (100 mg) were contacted with 0.2 mL of toluene saturated water solution (6×10^{-3} M, see experimental part). Table 2 shows that, after 10 min, about all the toluene present in solution was entrapped by Na₄W₁₀O₃₂/SiO₂/BTESE, whereas, in line with the adsorption measurements reported in Figs. 5 and 6, Na₄W₁₀O₃₂/SiO₂ entrapped toluene in a significantly lower degree (about 54%).

Each photocatalytic material containing toluene was then suspended in distilled water (0.5 mL) and irradiated (λ > 290 nm) for 30 min. Measurements with an ultraviolet radiometer indicated that the employed amount of photocatalyst absorbed more than 90% of the impinging radiation. Table 2 reports nature and yields of the detected products.

Both $Na_4W_{10}O_{32}/SiO_2/BTESE$ and $Na_4W_{10}O_{32}/SiO_2$ are able to photocatalyse the oxidation of toluene to CO_2 with only traces of benzyl alcohol and benzaldehyde as reaction intermediates. Control experiments indicated that no oxidation product was formed in detectable amount in the absence of light or irradiating the raw silica materials without decatungstate. Moreover, no CO_2 was formed irradiating $Na_4W_{10}O_{32}/SiO_2/BTESE$ in the absence of toluene, indicating that the organic part of BTESE did not undergo degradation during the photocatalyte experiment.

The strong mineralizing ability of the photocatalytic materials is in line with EPR spin-trapping findings, that evidence the

Table 2 Photocatalytic oxidation of toluene by $Na_4W_{10}O_{32}/SiO_2/BTESE$ and $Na_4W_{10}O_{32}/SiO_2$.

$Total\ \mu moles\ of\ reagents\ and\ products\ (\mu moles\ of\ reagents\ and\ products\ entrapped\ within\ the\ photocatalyst)\ [\%\ with\ respect\ to\ adsorbed\ toluene\ \mu moles]$				
Reagents and products	Na ₄ W ₁₀ O ₃₂ /SiO ₂ /BTESE	Na ₄ W ₁₀ O ₃₂ /SiO ₂		
Toluene before irradiation	1.20 (1.20)	1.20 (0.65)		
Toluene after irradiation	$4.8 \times 10^{-2} (2 \times 10^{-2}) [5.8\%]$	$7.6 \times 10^{-2} (4.3 \times 10^{-2}) [18.3\%]$		
CO ₂ ^b	1.1 [91.8%]	0.5 [77%]		
Benzyl alcohol	$4.7 \times 10^{-3} (1.6 \times 10^{-3}) [0.6\%]$	$1.9 \times 10^{-3} (1.2 \times 10^{-3}) [0.5\%]$		
Benzaldehyde	$1.1 \times 10^{-2} (0.9 \times 10^{-2}) [1.8\%]$	$1.6 \times 10^{-2} (1.1 \times 10^{-2}) [4.2\%]$		

^a In a typical experiment, $Na_4W_{10}O_{32}/SiO_2/BTESE$ or $Na_4W_{10}O_{32}/SiO_2$ (200 g/L) were contacted with toluene saturated water solution, then irradiated in distilled water ($\lambda > 290$ nm) for 30 min at 25 ± 1 °C and 1 atm of O_2 . Reported values are the mean of three repeated experiments (percentual error is $\pm 5\%$).

formation of OH $^{\bullet}$ radicals. These powerful and unselective oxidants are formed in the constrained environment of the photocatalysts pores, where restrictions of molecular motion may favour overoxidation of the primary photoproducts (benzyl alcohol and benzaldehyde) to CO₂. This assessment is further supported by the findings obtained irradiating Na₄W₁₀O₃₂ (2 × 10⁻⁴ M, 30 min, λ > 290 nm) dissolved in toluene saturated water solutions. Fig. 9 shows that, in this case, only 8% of initial toluene is converted to CO₂, indicating that, in these conditions, primary oxidation products are free to diffuse going away the photoactive decatungstate so preventing their subsequent oxidation.

Table 2 shows that, besides facilitating toluene entrapping, the hydrophobic nature of Na₄W₁₀O₃₂/SiO₂/BTESE affects positively also the photocatalytic activity, likely increasing the local concentration of toluene in close proximity of the photoexcited decatungstate. In fact, only 5.8% of the adsorbed toluene remains after irradiation and 91.8% of the disappeared toluene is converted to CO₂. On the contrary, 18.3% of the adsorbed toluene is recovered after irradiation of Na₄W₁₀O₃₂/SiO₂. It is worth noting that the efficiency of Na₄W₁₀O₃₂/SiO₂/BTESE is significantly higher than that of Na₄W₁₀O₃₂/SiO₂ if one considers both the sorption capability and the photocatalytic activity parameters. In fact, Fig. 9 indicates that the hydrophobic material is able to convert more than 90% of the toluene initially present to CO₂ while about 42% of toluene can be mineralized to CO₂ by Na₄W₁₀O₃₂/SiO₂.

The data of Table 2 show that the amount of benzyl alcohol entrapped within the two photocatalysts is different: as expected on the basis of hydrophobicity characteristics of the two photocatalysts, only 34% of formed alcohol is adsorbed by $Na_4W_{10}O_{32}/SiO_2/BTESE$ while 63% of benzyl alcohol remained in the hydrophilic $Na_4W_{10}O_{32}/SiO_2$. Therefore, the adsorbed alcohol can easily react with the photoexcited decatungstate and converted to benzaldehyde. This is confirmed considering the ratios between μ moles of benzaldehyde and benzyl alcohol with the two

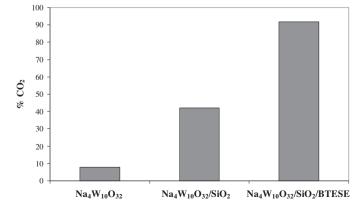

Fig. 9. % CO_2 formed from the starting toluene saturated water solution upon irradiation of $Na_4W_{10}O_{32}$, $Na_4W_{10}O_{32}/SiO_2$ or $Na_4W_{10}O_{32}/SiO_2/BTESE$ in aerated conditions.

photocatalysts. It is seen that the ratio is 3.2 for $Na_4W_{10}O_{32}/SiO_2/BTESE$ and increases up to 8.7 for $Na_4W_{10}O_{32}/SiO_2$.

Repeated experiments indicated that $Na_4W_{10}O_{32}/SiO_2/BTESE$ could be reused for further toluene extractions and subsequent irradiations. Each time the material was recovered, washed with water, acetone, acetonitrile and dichloromethane sequentially, and used again. The loss of activity in terms of both toluene sorption and photocatalytic degradation was within the experimental error (5%) after three repeated cycles. UV–vis spectra indicated that the decatungstate was not released in detectable amounts into the solution suggesting that the photocatalytic process was heterogeneous in nature. This assessment was confirmed by experimental evidences showing that, when the reaction filtrate was further irradiated, no additional formation of photoproducts was observed.

4. Conclusions

A new photocatalytic material has been prepared by entrapment of Na₄W₁₀O₃₂ inside porous organosilica. This material is able to scavenge and to accumulate significant amounts of toluene from toluene saturated water solutions. This is due to the large surface area of Na₄W₁₀O₃₂/SiO₂/BTESE, presence of micro and mesopores and, especially, to the hydrophobicity of its surface. Photoexcited Na₄W₁₀O₃₂/SiO₂/BTESE shows a very high efficiency since it adsorbs all the toluene present in solution and converts more than 90% of the adsorbed hydrocarbon to CO₂ with only traces of reaction intermediates. Likely, micro and mesopores cooperate to the photodegradation, since they can act as small microreactors, where both restriction of molecular motions and high hydrophobicity increase the contact between toluene and photoactive decatungstate groups. The close interaction favours the reaction of substrate (and reaction intermediates) with the photogenerated OH• radicals to yield CO₂ as final main degradation product. Considering both the sorption capability and the photocatalytic activity, the efficiency of $Na_4W_{10}O_{32}/SiO_2/BTESE$ is significantly higher than those of Na₄W₁₀O₃₂/SiO₂ and Na₄W₁₀O₃₂ dissolved in homogeneous solution. Finally, the photocatalyst Na₄W₁₀O₃₂/SiO₂/BTESE is robust and reusable without the need to recycle the material by calcining at high temperature. The above conclusions may open new perspectives for developing new efficient and stable photocatalytic systems addressed to clean wastewater containing aromatic hydrocarbons.
